Relationship between selenium and breast cancer: a case-control study in the Klang Valley

ABSTRACT

Introduction: The purpose of this study was to assess the relationship between selenium status and intake among breast cancer patients from the Klang Valley.

Methods: 64 cases and 127 controls were matched for age (range 30–65 years) and ethnicity, with an 80 percent study power. Subjects were interviewed to obtain information on their habitual dietary intakes, demographic data and medical history. Selenium status was determined from toenail and hair analysis using an inductively coupled plasma mass spectrometer.

Results: The nutrient analysis showed that total energy and protein intake was significantly higher among controls (1,403 +/- 367 kcal/day, 75.6 +/- 33.2 g/day) as compared to cases (1,273 +/- 295 kcal/day, 60.9 +/- 19.1 g/day) (p-value is less than 0.05). The selenium intake among cases (78.47 +/- 25.34 µg/day) was significantly lower than the controls (89.34 +/- 36.85 µg/day) (p-value is less than 0.05). Breast cancer risk decreased with the increasing quartiles of selenium intake, with odds ratios (95 percent confidence interval) of 2.95 (1.22–7.12), 2.17 (1.13–4.19) and 1.71 (0.84–3.52), respectively. However, the association diminished after adjustment for confounding factors. Selenium in hair did not differ among cases and controls, but selenium status in the nails of controls was significantly higher as compared to cases (p-value is less than 0.05). Breast cancer risk decreased with the increasing quartiles of toenail selenium status as measured in the toenail and hair.

Conclusion: Selenium intake and status was associated with breast cancer risk. Thus, it is essential for Malaysian women to achieve a good selenium status by consuming good food sources of selenium as a chemopreventive agent.

INTRODUCTION

Breast cancer is the third most common cancer worldwide and the most common cancer among women. In Malaysia, there were 3,738 female breast cancer cases reported in the year 2003, making it the most commonly-diagnosed cancer among women from all ethnic and age groups from the age of 15 years. The Chinese had the highest incidence, with an age-standardised incidence rate (ASR) of 59.7 per 100,000 population, followed by Indian women with an ASR of 55.8 per 100,000 population and Malay women with an ASR of 33.9 per 100,000 population. Antioxidants, including selenium, protect cells from DNA oxidative damage by scavenging free radicals in epithelial cells of the breast that can cause cancer. The relationship between selenium status and risk of cancer such as of the prostate, intestines, lung and liver has been documented in Western countries. However, its association with breast cancer remains a controversial issue. An earlier prospective study reported no association between selenium levels in toenails with breast cancer, however, a contradictory finding was reported in another study which found that low selenium status increased breast cancer risk by 1.24 times. Case-control studies have reported that selenium status as assessed via toenails is not associated with breast cancer, but significant findings were found in plasma levels and dietary selenium intake. Thus, investigations on the role of selenium in breast cancer are important in constructing chemopreventive strategies. The aim of this study is to identify the relationship between selenium status and breast cancer among women in the Klang Valley using a case-control approach. This study obtained ethical approval from the Ministry of Health of Malaysia and informed consent was obtained from subjects.

METHODS

The estimated sample size of 180 was calculated at 95%...
Subjects were asked for their demographical and socioeconomic information, past medical history, family history and reproductive data, including menstrual cycle, menopausal status, pregnancy and lactating history, consumption of oral contraceptive pill and hormone replacement therapy. Body weight (kg) was measured using the digital scale SECA (SECA, Germany) while height (m) was measured using SECA bodymeter (SECA, Germany). A measurement tape was used to measure the waist and hip circumference (cm). Body mass index (BMI) and waist:hip ratio (W:H) were derived from the measurements. All measurements were carried out according to the standard procedure. Food intake including selenium was assessed through a face-to-face interview using a validated Diet History Questionnaire (DHQ), and supplemented by a semiquantitative Food Frequency Questionnaire (FFQ). Cases were requested to report their eating habits before diagnosis. The interview included details for every meal or snack through the use of open-structured questions. A set of household measures was shown to the subjects to help in portion size estimation. In completing the FFQ, subjects were required to report the frequency of taking each food in the form of frequency per week.

Toenail and fingernail samples were collected from the subjects. Hair was cut randomly at different locations on the head. All samples were stored in sealed plastic bags at room temperature. Nail and hair selenium was measured using an Inductively Coupled Plasma Mass Spectrometer (ICP-MS) (model ELAN 6000, Perkin Elmer, Norwalk, USA), at the Institute for Medical Research, Kuala Lumpur. The preparation and analysis of samples were carried out by the Inductively Coupled Plasma-Atomic Emission Spectrometer, ICP-MS method. Hair and toenail samples were prepared by appropriate nitric (Aristar, BDH Laboratory, Poole, England) – perchloric (Merck, Darmstadt, Germany) acid digestion procedure. The basis of the method was the measurement of atomic emission by an optical spectroscopic technique. Samples were nebulised and the aerosol that was produced was transported to the plasma torch where excitation occurred.

Characteristic atomic-line emission spectra were produced by a radiofrequency inductively coupled plasma. The spectra were dispersed by a grating spectrometer and the intensities of the lines were monitored by photomultiplier tubes. The photocurrents from the photomultiplier tubes were processed and controlled by a computer system. A selenium standard (Merck, Darmstadt, Germany) was also run and a background correction technique was also required to compensate for variable background contribution to the determination of the trace elements. An American food database, i.e. Nutritionist Pro, was used to perform the diet analysis because Nutrient Composition of Malaysian Food does not contain selenium. The nutrient intake that was analysed included energy, fat, protein and selenium. The Statistical Package for Social Sciences version 12.0 (SPSS Inc, Chicago, IL, USA) was used to analyse the data. A significance level of p < 0.05 was adopted for hypothetical testing.

*p < 0.05, significant difference at two-tail independent t-test, SD: standard deviation
The risk of breast cancer was reduced and was found to be lower in women with a higher selenium status, accounting for confounding factors including education, working status, family history, lactation, and waist circumference. The adjusted OR (CI) for breast cancer risk at the 50th percentile was reduced to 1.56 (0.72–3.39). Selenium intake significantly differed among different ethnic groups, with Chinese subjects (94.3 ± 39.7 µg/day) having the highest intake, followed by Malays (83.4 ± 28.9 µg/day) and Indians (76.3 ± 33.9 µg/day) (p < 0.05). However, the selenium status did not differ significantly among ethnic groups. Nevertheless, the level of selenium in the nail and hair remained high in Chinese as compared to the Malays and Indians. The mean selenium level in nails of both groups was significantly associated with age, female gender, and Malay ethnicity. The OR was 0.487 (p < 0.05) for Malay ethnicity, 0.269 (p < 0.05) for female gender, and 0.103 (p < 0.05) for a younger age range. The energy intake of case subjects was lower (p < 0.05), with the mean energy intake being 2,180 kcal/day for case subjects and 1,780 kcal/day for control subjects.

For example, the adjusted OR (CI) of breast cancer risk at the 50th percentile was reduced to 1.56 (0.72–3.39). Selenium intake significantly differed among different ethnic groups, with Chinese subjects (94.3 ± 39.7 µg/day) having the highest intake, followed by Malays (83.4 ± 28.9 µg/day) and Indians (76.3 ± 33.9µg/day) (p < 0.05). However, the selenium status did not differ significantly among ethnic groups. Nevertheless, the level of selenium in the nail and hair remained high in Chinese as compared to the Malays and Indians. The mean selenium level in nails was significantly higher among control subjects compared to case subjects (p < 0.05). The adjusted OR for selenium intake was 0.487 (p < 0.05) for Malay ethnicity, 0.269 (p < 0.05) for female gender, and 0.103 (p < 0.05) for a younger age range. The energy intake of case subjects was lower (p < 0.05), with the mean energy intake being 2,180 kcal/day for case subjects and 1,780 kcal/day for control subjects.

For example, the adjusted OR (CI) of breast cancer risk at the 50th percentile was reduced to 1.56 (0.72–3.39). Selenium intake significantly differed among different ethnic groups, with Chinese subjects (94.3 ± 39.7 µg/day) having the highest intake, followed by Malays (83.4 ± 28.9µg/day) and Indians (76.3 ± 33.9µg/day) (p < 0.05). However, the selenium status did not differ significantly among ethnic groups. Nevertheless, the level of selenium in the nail and hair remained high in Chinese as compared to the Malays and Indians. The mean selenium level in nails was significantly higher among control subjects compared to case subjects (p < 0.05). The adjusted OR for selenium intake was 0.487 (p < 0.05) for Malay ethnicity, 0.269 (p < 0.05) for female gender, and 0.103 (p < 0.05) for a younger age range. The energy intake of case subjects was lower (p < 0.05), with the mean energy intake being 2,180 kcal/day for case subjects and 1,780 kcal/day for control subjects.

DISCUSSION
The energy intake of both cases and controls was below the Malaysian RNI, with controls reporting a higher intake. This could be due to the high percentages of under-reporters, especially among cases, i.e. 82.8% in cases and 67.7% in controls. They were not able to recall the food intake before being diagnosed with cancer or the disease process might have influenced the memory. The energy intake pattern found in this study goes against the findings of some local studies, where energy intake was found to be higher among cases as compared to controls.
controls.\textsuperscript{(16,17)} One cohort study (Nurses’ Health Study), which began in the United States in 1976, did not show any correlation between energy intake and breast cancer in postmenopausal and premenopausal women.\textsuperscript{(18)} Another case-control study among breast cancer women in Montreal also showed similar findings.\textsuperscript{(19)} The control subjects have a higher protein intake perhaps due to their higher energy consumption.

The selenium intake of cases (78.46 ± 25.34 µg/day) was lower than that of controls (89.34 ± 36.85 µg/day) (p < 0.05). In one local study that involved cancer patients at Hospital Kuala Lumpur, the mean selenium intake for cases (90.93 ± 71.25 µg/day) and controls (74.84 ± 44.94 µg/day) did not show any significant difference.\textsuperscript{(15)} The values of selenium intake in the present study and another local study\textsuperscript{(16)} were comparable to those reported among Americans, i.e. 80–120 µg/day.\textsuperscript{(20)} This is because the US food database was used in these studies. Selenium intake for subjects in this study was much higher than those reported in New Zealand (28–30 µg/day),\textsuperscript{(21)} East Croatia, (24.8 µg/day)\textsuperscript{(22)} and Andean Highland (36.6 ± 13 µg/day),\textsuperscript{(23)} but slightly lower than in South California (90–168 µg/day).\textsuperscript{(24)} Women from seleniferous areas, such as South Dakota and Wyoming, have a selenium intake of 128 ± 58 µg/day.\textsuperscript{(25)} Subjects in this study appeared to have moderate selenium intake as compared to other places. However, it should be borne in mind that the US Food Composition Table was used to analyse the selenium intake, and there might be some under- or over-reporting.

The risk of breast cancer decreased with the increasing quartile of selenium intake, with significant association noted at the 50th and 75th percentiles; however, the associations were not significant after adjustment for confounding factors. The opposite trend was found in one study, where the OR of breast cancer increased at the lowest and highest quartiles.\textsuperscript{(26)} Women in this study consumed selenium at higher levels than in the US RDA\textsuperscript{(16)} and RNI Malaysia,\textsuperscript{(13)} but lower than the recommended upper tolerable level, 400 µg/day.\textsuperscript{(27)} Only one subject (from the case group) had a low intake of below the Malaysian RNI of 25 µg/day. In this study, the Chinese had the highest selenium intake and status, followed by the Malays and Indians. This is because the Chinese consume pork, and among selenium-rich meat, pork has a higher level of selenium,\textsuperscript{(28)} followed by meat and fish.\textsuperscript{(29)} Pork consumption is prohibited by Malays or Muslims, whereas beef is not eaten among Indians. According to the USDA,\textsuperscript{(28,30)} the selenium level in pork is the highest, followed by beef, then lamb. It is important for non-pork eaters to increase their selenium intake by consuming good sources of selenium, such as wholegrain products, legumes, milk, seafood, fish and meat.

Selenium levels in the nail and hair of subjects in this study were quite low compared to previous studies.\textsuperscript{(31,32)} In one intervention study among 12 healthy men, a low selenium diet had lowered their hair selenium level from 0.36 ± 0.14 µg/g to 0.32 ± 0.02 µg/g, while a high selenium diet successfully increased hair selenium levels from 0.79 ± 0.46 µg/g to 0.90 ± 0.12 µg/g and remained constant at a certain level.\textsuperscript{(33)} Hair selenium level in this study was almost similar to the level caused by a low selenium diet, although the selenium intake levels of all the subjects were quite high. Inappropriate amounts of hair and nail samples or contamination might have caused the undetected concentration. In addition, the selenium intake estimated from the US Food Composition Table might be overestimated, as the level in American food might be higher than in Malaysian food. When the selenium intake is high until it is metabolically saturated, excessive selenium will accumulate in the nail.\textsuperscript{(31,32)} In this study, subjects had a selenium intake higher than the Malaysian RNI\textsuperscript{(13)} and USRDA,\textsuperscript{(16)} but nail selenium levels were lower than in other studies.

There are a few possibilities for what led to these findings. It might either be due to the high metabolic requirement of subjects or the fact that the RNI Malaysia was too low for this group. As a result, although their selenium intake was 300% higher than the RNI, there was no excessive selenium accumulation in their nails. Subjects in this study ate more cereal compared to seafood, and the bioavailability of selenium in plants is lower.\textsuperscript{(29,35)} This might be the cause of the low levels of selenium in the nail and hair. In addition, the chemical form of selenium in the diet plays an important role in affecting one’s selenium level because the bioavailability of selenium depends on the chemical form.\textsuperscript{(36)} However, no information about the chemical form of selenium in local food was available and therefore this factor could not be investigated in this study.

Selenium status was found to increase with selenium and protein intake, indicating the importance of dietary factors in obtaining a good selenium status. Another study also found a moderate correlation (r 0.53, p < 0.001) between the selenium level in nails and selenium intake.\textsuperscript{(22)} In conclusion, selenium intake and status are related to breast cancer risk. Therefore, selenium intake through the diet should be emphasised as a chemopreventive agent in reducing the risk of breast cancer. There is an urgent need to analyse the selenium content in Malaysian foods.
